Statement reviewed and approved by AAEM Board of Directors. (4/23/2022)

Executive Summary

Emergency departments (ED) and emergency medical services (EMS) are motivated to increase survival following sudden out of hospital cardiac arrest (OHCA).\(^1\) Extracorporeal cardiopulmonary resuscitation (ECPR) has been promoted as an option but substantial uncertainty exists regarding how to select patients.\(^2\) Recently, a single-center randomized controlled trial demonstrated increased survival with early extracorporeal membrane oxygenation (ECMO), compared to standard care.\(^3\) Limited evidence demonstrates some emergency departments have successfully implemented ECPR.\(^4\) The observational data is mixed. An overarching problem with existing data is the concept of competing risk. If OHCA patients are being moved to ECPR centers and this were to compromise the delivery of standard advanced cardiac life support measures to other patients, it is possible that ECPR strategies may decrease the survival of a population of OHCA patients. At this point in time, the existing evidence is not strong enough to recommend the use of ECPR for OHCA as a standard of care. Further research is needed, particularly on how the broader OHCA population would be affected.
Questions

In accordance with the AAEM template for structured clinical practice statements, we discussed the scope and plan for a literature review. Although ECMO has the potential to be applied to treat a range of conditions, such as refractory cardiogenic or pulmonary embolism-associated shock, we elected to focus on its use in refractory OHCA. Therefore, other indications for ED-based ECMO are not addressed in this statement.

Is ECMO more effective for refractory out of hospital cardiac arrest versus standard ACLS?

Although there have been some encouraging new studies, there is insufficient evidence to claim that ECPR is more effective than standard ACLS for OHCA at this time.

ECPR has been advanced as a method of increasing survival for OHCA. Prior work has uniformly studied a highly-selected subset of this population, one with a short-downtime or witnessed cardiac arrest, shockable rhythm, younger age, and an absence of severe comorbidities. However, prior to the ARREST trial, the available literature consisted of observational and registry studies without randomization and frequently retrospective in nature. The 2019 AHA Guidelines offer a weak recommendation for ECPR, stating, “ECPR may be considered for selected patients as rescue therapy when conventional CPR efforts are failing in settings in which it can be expeditiously implemented and supported by skilled providers,” albeit acknowledging a high risk of bias and heterogeneity among existing studies.

The ARREST trial, the first randomized controlled trial based on the single center experience of the University of Minnesota, showed positive results for ECPR over conventional cardiopulmonary resuscitation (CCPR) among 30 patients. Enrollment criteria included an initial shockable rhythm, no return of spontaneous circulation (ROSC) after three shocks and transfer time of less than 30 minutes. 6/14 in the ECPR group survived to hospital discharge vs 1/15 in the CCPR group (one patient withdrew from the study).

The results of the ARREST trial lead us to question whether ECPR should become the new standard of care for refractory cardiac arrest in suitable candidates where it is available. However, the number of participants in the study was small and the trial was stopped early. Accordingly, the confidence intervals for ECPR vs CCPR survival to hospital discharge intersect each other (43%, 21.3-67.7% compared with 7%, 1.6–30.2%, respectively), so meaningful uncertainty remains about its true efficacy.
Further, the protocol involved coordination with interventional cardiologists that immediately took the patients in the ECPR group to the catheterization laboratory upon hospital arrival, regardless of the presence of ROSC, in order to initiate ECMO and revascularize occluded coronary arteries. The presence of ROSC at any point after 3 shocks had been administered was not an exclusion criteria for the study. This could potentially have skewed results in favor of ECPR, since patients that had achieved ROSC without ECMO likely would not receive coronary angiography as expeditiously as such patients in the ECMO treatment arm.

Other observational studies utilizing an assortment of systems for administration of ECPR have reported varying results. Hsu et al in a single center study of 30 patients from the University of Michigan, reported 0% survival in the 5/15 patients that received ECPR. Bourgoin et al, showed better survival with ECPR with refractory shockable rhythms, based on a Parisian OHCA registry. Lamhaut et al, also reporting on a Parisian registry utilizing mobile intensive care units showed higher survival with ECPR once stringent patient selection criteria and an aggressive (ECPR if > 20 minutes without ROSC) protocol were instituted. Alm-Kruse et al, in another registry study from Oslo, demonstrated no improvement with ECPR, and possibly harm, although not statistically significant, despite selecting for patients with shockable rhythms, younger age, and shorter CPR times.

A prospective observational study investigating the natural history of conventional resuscitation among theoretically ECMO-eligible patients may be helpful in setting a benchmark for assessing the effectiveness of ECPR programs. 11% of 1237 patients were eligible for the cohort and 38% survived to hospital discharge, 30% with a good neurologic outcome. Such numbers are better than the commonly reported 14-31% range for survival in OHCA due to VF/VT and suggest a standard against which to compare outcomes from ECPR trials.

As stated by some of the authors of the above papers, instituting an effective ECPR program requires the reorganization of the local prehospital system to rapidly triage patients who would benefit from early ECMO treatment. It is thought that shorter intervals before cannulation for ECMO are associated with better survival. This necessitates the initiation of emergency transport to an ECMO-capable center after a pre-specified on-scene time or other criteria indicating refractoriness to standard ACLS measures. In some programs, 15 minutes without ROSC was a criteria to initiate ECMO transport. What is not clear is what effect such reorganization of prehospital care would have on the overall survival of cardiac arrest patients. The Alm-Kruse study may be a cautionary one, in which post-ECPR implementation survival was actually lower among ECPR-eligible patients, compared to the pre-implementation time period, although the findings were not statistically significant. The authors theorize that since patients have been shown to have worse outcomes with in-transport CPR, compared with on-scene CPR, the mandatory transport of patients after 10 minutes without ROSC potentially led to worse survival and may have had a paradoxically negative effect in the study. The effect of transporting a larger number of patients with CPR in progress must be considered in light of a recent large multi-center propensity-matched observational study where intra-arrest transport was associated with worse overall and neurologically-intact survival.
Conclusions

Encouraging data on ECMO for OHCA continues to trickle in, especially with the addition of the first randomized trial in 2020, but study participant numbers remain small and not sufficiently convincing to disturb the current equipoise. Therefore, ECMO for OHCA cannot be recommended as superior to standard ACLS, even in centers where it is available, until additional randomized trials reproduce the results of the ARREST trial. Further, improvements in survival with ECPR must not come at the expense of worse outcomes in the much larger total OHCA population.
